**Reply to Referee's Report n. 1 on ANOR-2216**  
**"Credit Quality and CDS volatility: the key signal"**

We are very grateful to the anonymous Referee who provided us with valuable suggestions to improve the current version of the paper. We were able to take into account all the comments reported and tried to prepare a new version of the paper.

Please find below our reply to specific comments:

- 1) Regarding the information provided by the abnormal returns we think an additional contribution is given. In the analysis we presented a distinction between the effect of rating announcements on CDS quotes for different rating class companies. In particular, using the E-GARCH model to estimate volatility yielded to prove that for A rated companies an anticipation of the downgrading occurs on average sixty days before the event, while for B rated companies a shortest anticipation occurs.
- 2) Regarding the presence of contamination, we have better described the type of data we used and make sure we were able to work with a data set in which overlapping of events had been removed. During the period of the analysis we would have had a much larger dataset if we had used all the rating events occurred in the markets. A long, clean-of-events estimation period was used to study each company's behavior.
- 3) The use of the Norden-Weber (2004) approach to use CDS index benchmarks to account for the systematic risk was taken into account in our previous study, Castellano and D'Ecclesia, 2011. We considered the excess return of each CDS quote with respect to the corresponding CDS indexes, ITRAXX or CDX, depending on whether the company was located in the US or Europe, The results obtained were non-conclusive and in our

opinion this was due to the nature of the CDS indices which do not take into account the different rating classes of the companies, which in our opinion provide a crucial contribution to the understanding of market creditworthiness.

- 4) Regarding the quality of the estimates for the E-GARCH model we were able to run a sensitivity analysis in order to validate the stability of the results obtained. Moving from 210 data to 350 data (as it is shown in section 4 , Figures 3-8) the E-GARCH parameters do not result statistically different, providing support to the use of E-GARCH model using the original Estimation period + Test period.
- 5) The use of the method suggested by Andersen, T., Bollerslev, T., Diebold, F.X. and Vega, C. (2003), in "*Micro Effects of Macro Announcements: Real-Time Price Discovery in Foreign Exchange,*" *American Economic Review*, 93, 38-62, will be considered in the subsequent paper where we would like to investigate the presence of structural breaks in the variance dynamics making different assumptions for different classes of rating. The purpose of the current paper is to overcome the limits of the standard Events Study Methodology which is based on the use of constant volatility which cannot be applied to the CDS cases.
- 6) The calculation of returns using the difference between CDS quotes has the specific role of providing information on the creditworthiness of the company given the nature of the quote. The difference between the CDS quote and the benchmark provides immediate information on the spread investors require to protect from the worst credit quality. Using the percentage returns would have yielded different information.

## **Reply to Referee's Report n. 3 on ANOR-2216**

### **“Credit Quality and CDS volatility: the key signal”**

We are very grateful to the anonymous referee who provided us with valuable suggestions to improve the current version of the paper. We were able to take into account all the comments reported and tried to prepare a new version of the paper.

Please find below our reply to specific comments:

- 1) The amount of data was constrained by the need to remove any contamination provided by the presence of overlapping events. We were able to work with a data set in which overlapping events had been removed. So a long, clean-of-events estimation period was used to study each company's behavior. We were able to run a sensitivity analysis in order to validate the stability of the results obtained. Moving from 210 data to 350 data (as is shown in section 4 , Figures 3-8) the E-GARCH parameters do not prove statistically different, providing support to the use of E-GARCH models using the original Estimation + Test period.
- 2) We have extended the length of the Estimation period up to 150 days only where possible, given the constraints mentioned in 1. No significant difference was observed in the results. Therefore we conclude that a 100 day length for the Estimation Period is able to provide an accurate estimation of what can be defined as “normal” behavior of the CDS quotes.
- 3) The purpose of the current paper is to overcome the limits of the standard Events Study Methodology which is based on the use of constant volatility which cannot be applied to the CDS case. The use of the method suggested by Andersen, T., Bollerslev, T.,

Diebold, F.X. and Vega, C. (2003), in "*Micro Effects of Macro Announcements: Real-Time Price Discovery in Foreign Exchange*," *American Economic Review*, 93, 38-62, will be considered in the subsequent paper, where we would like to investigate the presence of structural breaks in the variance dynamics making different assumptions for different classes of rating.

- 4) We have provided additional evidence of differences between A-rated and B-rated companies in the current version of the paper also adding more evidence of the different behavior of the conditional volatility for the various rating classes. In our opinion the main contribution of the analysis is to highlight how the rating class affects investor's behavior.
- 5) Unfortunately it was not possible to test separately for reviews that lead to a rating change versus all reviews. given the size of the sample.
- 6) In the sample we used we avoided any presence of contamination, as highlighted in 1). In this respect, the reaction around downgrades cannot be attributed, in this analysis, to the fact that most of the reviews are followed by a downgrade and the average distance between the two events is 44 days.

# CDS Volatility: the Key Signal of Credit Quality

Rosella Castellano\*, Rita L. D'Ecclesia<sup>†</sup>

## Abstract

This paper investigates the role of CDS volatility in providing information concerning the credit quality of a company.

In Castellano and D'Ecclesia (2011) a first analysis of how CDS quotes respond to rating announcements is provided and it showed that market participants do not rely much on Rating Agencies, especially during periods characterized by very high volatility, i.e. during a financial crisis. Here, a more accurate analysis of the CDS's ability to provide timely information on the creditworthiness of reference entities is performed, estimating the volatility of CDS quotes by using Exponential GARCH(1,1) models. The event study methodology is applied to a sample of CDS quotes for US and European markets, over the period 2004-2009. Results provide an accurate understanding of market behavior in the presence of news released by Rating Agencies. Overall, market participants seem to provide timely reactions around the event date and we show that the key element of signaling is represented by the changing volatility in CDS quotes, before and after the rating event.

JEL Classification Numbers: G14, G01, G12, C58.

Keywords: Credit Default Swaps; Event Study; Exponential GARCH.

## 1 Introduction

The effect of rating announcements on financial market dynamics has been widely discussed in the literature. Earlier studies concentrated on the analysis of stock and bond price dynamics and investigated how rating changes

5  
6  
7  
8  
9 could affect market behavior (Bremer and Pettway, 2002; Steiner and Heinke,  
10 2001; Gropp and Richards, 2001; Kliger and Saring, 2000; only to cite a few).  
11 The introduction of Credit Default Swaps (CDSs) provides useful information  
12 regarding the creditworthiness of a company. Consequently the analysis of how  
13 rating changes may affect CDS quote dynamics may reveal additional informa-  
14 tion regarding the investor's perception of the changing creditworthiness of a  
15 company. When pronouncing on an issuer's creditworthiness, rating agencies  
16 face a trade-off between timeliness and possibly creating adverse volatility. In-  
17 formation to assess an issuer's creditworthiness arrives at a high frequency, and  
18 so credit ratings must be continually updated since they have to incorporate the  
19 latest information. Rating agencies attempt to balance these conflicting goals  
20 by making multiple announcements, some of which reflect the latest information  
21 and others, following the through-the-cycle methodology, provide a stable signal  
22 of credit quality.  
23  
24  
25  
26  
27  
28  
29  
30

31 In Castellano and D'Ecclesia (2011) the effects caused by rating announce-  
32 ments (rating changes and reviews) on CDS quotes have been analyzed using  
33 standard Event Study methodology. The results of the analysis were not al-  
34 ways in line with expectations and, in some cases, inconclusive. In some studies  
35 (Norden and Weber, 2004; Hull et al., 2004; to cite the most relevant) evidences  
36 of abnormal changes in CDS quotes have been found, showing that markets  
37 anticipate rating announcements in case of "bad news". In addition, in most  
38 cases no post announcements effects were found. Some other studies (Micu et  
39 al. 2006) find that reviews, rating changes and outlooks affect market behavior  
40 and the market does not anticipate any rating agency actions.  
41  
42  
43  
44  
45  
46

47 In our opinion, the aforementioned studies have a major constraint as they  
48 assume constant volatility of market quotes, while heteroscedasticity often char-  
49 characterizes the real market. Hence, the assumption of constant volatility causes  
50 biases in the results. When bad news on creditworthiness reach the market,  
51 CDS quotes increase and, in line with the volatility clustering issue, also the  
52 volatility of CDS quotes increases. Castellano and Scaccia (2010, 2011) relax  
53 the assumption of homoscedasticity by exploiting the ability of Hidden Markov  
54 Models to model state-dependent means and variances of CDS returns. They  
55 find that CDS return series build around negative rating events are characterized  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

2  
3  
4  
5  
6  
7  
8  
9 by very different temporal dynamics. This heterogeneity may cause a general  
10 underestimation of the market anticipations and reactions, when abnormal re-  
11 turns are cumulated over time and averaged over series as in classical Event  
12 Study analysis.  
13  
14

15 In this paper, we extend Castellano and D'Ecclesia (2011) results, by tak-  
16 ing into account the role played by stochastic volatility. Following Yamaguchi  
17 (2008), and Corhay and Rad (1996), we estimate the volatility of CDS quotes  
18 using the E-GARCH models (Nelson, 1991) and we then use the Event Study  
19 methodology to investigate market reactions. This approach offers a more re-  
20 liable instrument to interpret the signals supplied by CDS markets trough the  
21 exploitation of the information linked with stochastic volatilities and CDS re-  
22 turn levels, which allow to identify abnormal market conditions.  
23  
24  
25  
26  
27

28 The analysis is performed using a larger set of data than previous stud-  
29 ies and the effects of rating announcements, reviews and effective changes, on  
30 CDS quotes are investigated. The data covers the period 2004 - 2009 for 60  
31 international companies belonging to different credit grades.  
32  
33

34 The paper is organized as follows: in Section 2, some relevant literature in  
35 rating announcements is reviewed; Section 3 describes the methodology, showing  
36 the importance of introducing E-GARCH estimations to measure the conditional  
37 variance of abnormal spread changes; Section 4 describes the data set, while  
38 Section 5 provides a brief description of the results; finally, Section 6 reports  
39 our conclusions.

## 45 **2 Some recent literature**

46  
47

48 The main goal of credit rating is to facilitate the comparison of an issuer's  
49 underlying long-term creditworthiness by means of standardized categories, so  
50 rating decisions are typically not influenced by events whose impact on credit  
51 quality is expected to be temporary (Micu et al., 2006; Weinstein, 1977). For  
52 this reason, rating agencies provide various kinds of announcements. Outlooks  
53 and reviews were introduced in the 80's to meet investor demand for more timely  
54 indicators and forewarn investors of possible changes in creditworthiness. More  
55 precisely, outlooks reflect the likely direction of an issuer's credit quality over  
56  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4  
5  
6  
7  
8  
9 the medium term (usually two years). It is modified when a change in the  
10 issuer's risk profile is observed, but it is not regarded as permanent enough to  
11 review the credit rating. Reviews, on the other hand, provide stronger signals  
12 than outlooks about future changes in rating, highlighting a high probability  
13 of upgrading or downgrading. Reviews are usually concluded within 90 days,  
14 after the receipt of additional information, clarifying the impact of a particular  
15 event on credit quality. Credit ratings need not be on review to be changed so  
16 reviews or changes in outlook do not always imply changes in rating.  
17  
18  
19  
20

21 The variety of research papers related to our study is diverse. The effects  
22 of rating announcements on market quotes have been investigated mainly using  
23 stock (Best, 1997; Akhigbe et al., 1997) and bond prices (Bremer and Pettway,  
24 2002; Gropp and Richards, 2001; Kliger and Sarig, 2000). Since bond markets  
25 are related to credit markets, results obtained for bond markets can be directly  
26 compared to those obtained for CDS markets.  
27  
28  
29  
30

31 Covitz and Harrison (2003) estimate that almost 75 per cent of the changes in  
32 bond prices occur six months before the rating downgrade. Only few studies find  
33 that rating announcements have different effects on equity markets compared  
34 to credit markets. Goh and Ederington (1993) find that the potential impact  
35 of rating announcements on equity prices is ambiguous and depends on the  
36 motivation of the announcement. When rating announcements are motivated by  
37 changes in the issuer's financial perspectives, they should have the same impact  
38 on equity and bond markets; negative (positive) rating announcements should  
39 cause a fall (rise) in equity prices. By contrast, rating announcements caused  
40 by changes in leverage should have opposite effects in equity and bond markets;  
41 negative (positive) announcements motivated by an increase in leverage should  
42 result in a rise (fall) in equity prices. Kliger and Sarig (2000) find that rating  
43 announcements cause bond and equity prices to move in opposite directions.  
44  
45  
46  
47  
48  
49  
50

51 As we focus on the effects that ratings announcements have on CDS quotes,  
52 we mainly refer to studies which have been applied to similar data sets, including  
53 Hull et al. (2004), Norden et al. (2004), Ammer and Clinton (2004), Micu et  
54 al. (2006), and Ismailescu and Kazemi (2010). Hull et al., (2004) and Norden  
55 et al., (2004), conclude that the reaction of CDS prices is most pronounced in  
56 the case of reviews for downgrade. Ammer and Clinton (2004) conclude for  
57  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4  
5  
6  
7  
8  
9 a significant negative reaction of asset-backed securities' prices to downgrades.  
10 Generally, with a few notable exceptions (Katz et al., 1974; Kliger and Sarig,  
11 2000; Micu et al., 2006), findings show that upgrades or reviews for upgrade do  
12 not have a significant impact on prices. Ismailescu and Kazemi (2010) find that  
13 CDS markets anticipate negative events while positive events have a positive  
14 impact on CDS markets only in the two day period surrounding the event.  
15 Even though results show that negative announcements impact prices, most of  
16 the price adjustments takes place before the announcements.  
17  
18  
19  
20  
21  
22

### 23 **3 The Event Study methodology**

24  
25  
26 Empirical tests of market efficiency examine price adjustments before, during  
27 and after a rating announcement. In short, if credit ratings convey new infor-  
28 mation, prices should react after a rating event causing CDS quotes to increase  
29 in the presence of a deterioration in the creditworthiness of a company. Since  
30 increases in CDS quotes cause changes in the volatility level in line with the  
31 argument of volatility clustering, this has to be taken into account when esti-  
32 mating abnormal CDS spread changes with respect to a chosen benchmark.  
33  
34  
35  
36

37 The aim of this paper is to investigate the effects of rating announcements  
38 on CDS markets in the presence of stochastic volatility. We expect significant  
39 positive changes in CDS quotes, together with an increase in volatility's level,  
40 at or after the negative rating events (the opposite holds for positive rating  
41 events). In some cases, credit markets may anticipate rating announcements  
42 and so abnormal performances may be detected before the event.  
43  
44  
45  
46

47 The following hypothesis are made:

- 48  
49
- 50 • Markets react after *review announcements* because they reveal new in-  
51 formation. Reviews in most cases anticipate the actual rating changes,  
52 therefore markets should react. No effective reactions are therefore ex-  
53 pected around actual rating changes following the reviews.  
54
  - 55 • Markets react only after *rating change announcements* and do not show  
56 any abnormal reaction before it.  
57  
58  
59

60 The results presented in Castellano and D'Ecclesia (2011) show that, in some  
61  
62  
63  
64  
65

1  
2  
3  
4  
5  
6  
7  
8  
9 cases, changes in CDS quotes may not have reflected announcements made by  
10 rating agencies. This has been particularly true in periods of very volatile quotes  
11 such as during the recent financial crisis. Standard Event Study methodology  
12 assumes constant volatility of abnormal returns and this may cause bias in the  
13 results. In financial time series it has been proven that volatility clustering  
14 occurs, so that in period of large changes, volatility reaches high levels. In order  
15 to take into account the role played by the volatility of CDS quotes, in this  
16 paper we suggest to use an E-GARCH model.

17  
18  
19 The main idea is to compare, for each reference entity  $i$ , the CDS daily  
20 changes, defined as  $S_{i,t}$ :

$$21 \quad S_{i,t} = CDS_{i,t} - CDS_{i,t-1} \quad (1)$$

22  
23  
24 with some chosen benchmark, assuming that residuals can be measured by E-  
25 GARCH models.

26  
27  
28 The chosen benchmark for each reference entity  $i$ , for the purpose of our  
29 analysis, is the mean change,  $E(S_{i,0})$ , computed over a period of "normal be-  
30 havior" identified as the estimation period.

31  
32  
33 Following Armitage (1995), to capture the effects of any rating announce-  
34 ment on CDS quotes we define:

- 35 • the event date,  $t^* = 0$ , for a sample of CDS subject to rating announce-  
36 ments;
- 37 • the estimation period,  $EP$ , where the "normal behavior" or "bench-  
38 mark" of CDS changes is measured;
- 39 • a test period,  $TP$ , or event window where the abnormal reactions of  
40 CDS quotes to announcements are analyzed.

41  
42  
43 The  $EP$  in this analysis has to be chosen in order to have a time span which  
44 could provide an efficient measure of normal behavior, given the large number  
45 of rating events occurred. For the sample of data used in this paper an interval  
46 of 100 days results to be the average maximum length to identify what can  
47 be considered normal behavior. The  $TP$  is set equal to 110 days divided in 6  
48 subintervals:

$$49 \quad I_j = [t_j, t_{j+1}]; \quad \text{for } j = 1, \dots, 6$$

50  
51  
52 Each  $I_j$  measures the number of business days before, after and around the

1  
2  
3  
4  
5  
6  
7  
8  
9 rating announcement;

10 An example of EP and TP is reported in the following scheme:

11  
12  
13 INSERT SCHEME ABOUT HERE  
14

15 The effective abnormal spread changes are calculated within the TP (for  
16 further details see Norden and Weber, 2004) which starts 90 business days before  
17 the event's occurrence,  $t^* = 0$ , and ends 20 business days after the event.  
18  
19

20 We test the following hypothesis:

- 21  
22
- 23 • If rating announcements are fully anticipated, then CDS quotes should  
24 adjust prior to the announcement in one of the four subintervals,  $I_1, \dots, I_4$ .  
25
  - 26 • If no anticipation occurs, announcements should have an effect on quotes  
27 only around the day of the event, i.e. subinterval  $I_5$ .  
28
  - 29 • In cases of illiquidity, the impact of rating announcements might be de-  
30 layed to  $I_6$ , i.e. after the event occurrence.  
31  
32  
33  
34  
35

### 36 37 3.1 Abnormal spread changes

38  
39 In order to investigate the effects of an event it is necessary to evaluate the ab-  
40 normal spread,  $AS_{it}$ , which measures the difference between the realized returns  
41 in the TP and the chosen benchmark:  
42  
43

$$44 AS_{it} = (S_{i,t} - E(S_{i,0})). \quad (2)$$

45  
46 After totalling the abnormal spreads of firm  $i$ , for each  $t$ , the cumulative abnor-  
47 mal spreads,  $CAS_i$ , are calculated over the various subperiods,  $I_j, \forall j = 1, \dots, 6$  :  
48  
49

$$50 CAS_i [I_j] = \sum_{t \in I_j} AS_{it}. \quad (3)$$

51  
52 The cross-sectional average  $CAS$  can be computed for each subperiods,  $I_j$ , and  
53 all the firms,  $i$ :  
54  
55

$$56 ACAS [I_j] = \sum_{i=1}^{N_s} \frac{CAS_i [I_j]}{N_s} \quad (4)$$

57 where  $N_s$  is the number of firms subject to disclosure.  
58  
59  
60  
61  
62  
63  
64  
65

1  
2  
3  
4  
5  
6  
7  
8  
9 **3.2 Volatility dynamics**

10  
11 We assume that abnormal spreads,  $AS_{it}$ , are conditionally heteroscedastic:

12  
13 
$$AS_{it} = \varepsilon_{it} | \Psi_{i,t-1} \sim N(0, h_{it}) \tag{5}$$

14  
15  
16 According to Batchelor and Orakcioglu (2010), three sources of heteroscedasticity may be observed. The first two are well recognized in the Event Study literature, while the third is very familiar in empirical finance, but relatively neglected in Event Study applications.

First, the model pools data from a number of different companies and time periods. The classical Event Study methodology means one necessarily constrains the effects of rating announcements on CDS abnormal spreads to be equal across companies. However, the variance of  $AS_{it}$  may not be constant across companies subject to disclosure. As it is shown in Figures 1 and 2, we observe sizable differences in the behavior of variances of abnormal CDS spreads for the companies in the sample. This type of heteroscedasticity can be easily handled by normalizing the data – that is, by dividing all the observations on each company or event by the standard deviation of observations across that company.

INSERT FIGURE 1 ABOUT HERE

(Figure 1.  $AS$  over the EP+TP period around a specific event).

INSERT FIGURE 2 ABOUT HERE

(Figure 2.  $AS$  over the EP+TP period around a specific event).

Second, there is no reason why the variance of abnormal spreads should be constant throughout the TP. Indeed, previous results by Castellano and D’Ecclesia (2010) did not provide any support to the hypothesis of specific effects of rating announcements, mainly because a constant variance assumption was made. In our opinion, an adequate Event Study analysis has to consider a time varying variance over the pre- and post-event periods. In principle, this may be handled through data normalization – for instance, by dividing each observation not by the whole-event sample standard deviation, but by

the standard deviation within the relevant inside-event window to which the observation belongs, as suggested by Boehmer et al. (1991). Heteroscedasticity of this kind is termed "event induced conditional heteroscedasticity".

Third, the GARCH model of Bollerslev (1986) has been found to provide a good description of the variance in daily stock returns (see, for instance: Akgiray, 1989; de Santis and Imrohorglu, 1997). In GARCH models, any large shock to a share price which causes an exceptionally high or low abnormal return on a particular day, also causes the variance of returns to be high on the following day, and to decay slowly back to its long run average 'unconditional' value. So, if a dividend event causes a large mispricing on the post-dividend day, say, prices are likely to be volatile for many days thereafter. Although there is much discussion of *event-induced variance* in the Event Study literature (Batchelor and Orakcioglu, 2010), few studies take the step of modelling the variance of returns through a GARCH process, given the large computational problems which may arise.

Assuming that the  $AS_{it}$ , are conditionally heteroscedastic

$$\varepsilon_{it} = \sqrt{h_{it}} \cdot z_t \quad z_t \sim N(0, 1) \quad (6)$$

we find that the E-GARCH(1,1) specification proposed by Nelson (1991) adequately fits the volatility process,  $h_{it}$ , of the sampled series:

$$\ln(h_{it}) = \alpha_i + \beta_{1i} \left| \frac{\varepsilon_{it-1}}{\sqrt{h_{it-1}}} \right| + \beta_{2i} \frac{\varepsilon_{it-1}}{\sqrt{h_{it-1}}} + \eta_i \ln(h_{it-1}). \quad (7)$$

The main feature of the E-GARCH models is that in [7] the log of the variances,  $\ln(h_{it})$ , will be positive regardless of whether the coefficients on the right side are positive. The conditional variance (7) is constrained to be non-negative by the assumption that the logarithm of  $h_{it}$  is a function of past innovations,  $\varepsilon_{it}$ . The second and third term in the RHS take into account the magnitude and the sign of  $\varepsilon_{it}$ . This enables  $h_{it}$  to respond asymmetrically to positive and negative values of  $\varepsilon_{it}$ . This feature is very important to model the behavior of CDS's spread changes (i.e. positive changes of CDS show a worsening in the credit quality of a company and vice versa).

After estimating the parameters in [7], we can obtain the conditional variance,  $h_{it}$ , for each firm,  $i$ , and time  $t$ . To apply Event Study methodology, the average variances over each subinterval,  $I_j$ , are estimated:

$$\bar{h}_i(I_j) = \frac{\sum_{t \in I_j} \exp(h_{it})}{N_{I_j}} \quad j = 1, \dots, 6 \quad (8)$$

where  $N_{I_j}$  is the number of days in each corresponding time interval. The cross sectional variance of the average  $CAS$  is given by:

$$VAR[ACAS(I_j)] = \frac{1}{N_s} \sum_{i=1}^{N_s} \bar{h}_i(I_j).$$

A cross-sectional  $J$ -test aimed at verifying the null hypothesis,  $H_0$ , that the event does not affect the spread changes ( $H_0 : AS_{it} = 0$ ;  $H_1 : AS_{it} \leq 0$ ) is defined by:

$$J = \frac{ACAS[I_j]}{\sqrt{\frac{1}{N_s-1} VAR[ACAS(I_j)]}} \quad J \sim N(0, 1).$$

## 4 The data set

The data set is entirely obtained from Bloomberg and consists of:

- 5 years maturity single name (CMA) CDS daily quotes<sup>1</sup> over the period 2004-2009;
- credit rating data and events, considering effective rating changes and reviews, provided by the three major international rating agencies, Standard & Poors, Fitch and Moody's.

The total sample is composed of 89.103 CDS quotes linked to 60 firms, 32 from Europe and 28 from the USA. All the 60 market-wide CDS contracts refer to senior unsecured reference obligation. Companies are further divided into different rating classes to investigate the possibility of different reactions to rating announcements.

Negative rating events clearly dominate the period given the occurrence of financial crisis. The total number of events we were able to select for our analysis is 420. The events were selected taking into account the size of the Estimation Period in order to avoid the presence of overlapping events. It is worth noticing here that, even though most of the announcements for the same company are

---

<sup>1</sup>The CMA database quotes lead the price discovery process in comparison with quotes provided by other databases (Mayordomo et al., 2010)

7  
8  
9 released by each credit rating agency in different days, in some cases announce-  
10 ments were released simultaneously. In order to avoid contamination effects  
11 due to simultaneous or multiple rating events in the TP and EP, we start with  
12 the first rating event for each firm and analyze subsequently TP and EP which  
13 include only one observation of a particular event type. A description of the  
14 sample is reported in Table 1.

INSERT TABLE 1 ABOUT HERE

We selected 420 events of which 155 reviews and 265 rating changes. Out of 155 reviews, 120 were followed by an effective rate change (either downgrading or upgrading). The average number of days between a review and an effective rate change was 44 days. More than the 80% of the events refer to a worsening in credit quality, i.e. reviews for downgrading or downgradings. Precisely:

- 132 negative reviews out of 155 (85%);
- 228 downgradings out of a total of 265 (86%) actual rating changes (positive or negative).

The largest occurrence of negative events was during 2007-2009. As would be expected. S&P and Moody's were almost equal in the number of events for each class and both provide a larger set of announcements than Fitch.

#### 4.1 Dynamics of CDS changes

In Table 2 some statistics regarding the CDS average daily spreads by class of rating are reported.

INSERT TABLE 2 ABOUT HERE

It is interesting to note that, on average, daily CDS spreads increase with the reduction of credit quality. However, we should point out that when looking at speculative grade companies, the expected relationship between CDS quotes and credit quality is violated, highlighting the presence of cases of spread reversal. For instance, the average spread for *B rated* companies is lower than the average spread for *Ba rated* companies.

1  
2  
3  
4  
5  
6  
7  
8  
9 The abnormal spread changes over the sample period show no stationarity.  
10 A preliminary study of the stationarity of the  $AS_{it}$ , was performed<sup>2</sup>. All the  
11 series of Abnormal Spreads for each of the examined companies, were found to  
12 be  $I(1)$ , as can be seen clearly in Figure 1 and 2. To estimate for each company  
13 the variance of the abnormal spread changes we use the E-GARCH(1,1) model.  
14 Precisely, the E-GARCH(1,1) variance is estimated by maximum likelihood us-  
15 ing the 210 day interval (EP+TP).  
16  
17  
18  
19

20 For each company, the model performs well and almost all of the E-GARCH(1,1)  
21 parameters were statistically significant. Table 3 reports the percentages of sta-  
22 tistically significant parameters and the percentages of positive parameters for  
23 the 210 day interval, divided by rating class and region. The tested null Hy-  
24 pothesis is  $H_0 : \theta = [\alpha, \beta_1, \beta_2, \eta] = 0$ .  
25  
26  
27

28 The E-GARCH(1,1) model performs well for both downgrades or reviews.  
29 For each estimated vector  $\theta$ , the parameters,  $\beta_1, \beta_2, \eta$  and  $\alpha$  were found to be  
30 statistically significant more than 80% of the time. Some differences were found  
31 between *A rated* and *B rated* companies. In the former case, the percentage  
32 of significance is higher for the GARCH parameter,  $\beta_1$ , (100%); while in the  
33 latter it is higher for the leverage parameter,  $\beta_2$ , (90,2%). So the variance of  
34 CDS quotes for *A rated* companies depends more on the size of the abnormal  
35 spread changes, while in the case of *B rated* companies the sign of the spread  
36 changes has higher impact. We may state that in the case of *A rated* companies  
37 a rating event causes large changes in CDS quotes which affect the variance  
38 behavior and, in the case of *B rated* companies, the sign of the changes may  
39 have a relevant influence.  
40  
41  
42  
43  
44  
45  
46

47  
48 INSERT TABLE 3 ABOUT HERE  
49

50 In order to test the robustness of the estimation we performed a sensitivity  
51 analysis by considering larger time intervals of up to 350 days. In this way  
52 we are able to study how the E-GARCH parameters change with increasing  
53 interval length. For each company and each event, the vector of parameters  
54  $\theta$  was estimated using different time intervals  $t_s$ ,  $s = 1, \dots, 5$ . Where  $s = 1$   
55 refers to the initial time length,  $t_1 = 210$ . The interval length is increased  
56  
57  
58

59 <sup>2</sup>The results of the ADF test performed on each company  $AS_{it}$  series around every event  
60 are not reported in the article but available upon request.  
61  
62  
63  
64  
65

of 35 days each time  $s$  is increased, in order to have  $t_2 = 245$ ,  $t_3 = 280$ ,  $t_4 = 315$ ,  $t_5 = 350$ . For each element of  $\theta$ , a  $t$ -test was used to investigate possible significant differences due to the different time length. The  $t$ -statistics estimated to test the null hypothesis ( $H_0 : \theta_{t_s} = \theta_{t_{s+1}}$ ) yield no statistically significant results. For each company, using the vectors of parameters  $\theta_{t_s}$  the conditional variance in Equation (7) was also estimated.

Some examples of the estimated parameters for a sample of *A rated* companies using different time intervals are reported in Figures 3, 4 and 5. Figures 6, 7 and 8 show the same for *B rated* companies.

INSERT FIGURES 3, 4 and 5 ABOUT HERE

INSERT FIGURES 6, 7 and 8 ABOUT HERE

The E-GARCH(1,1) variance of the  $AS_{it}$ , for each event, is defined by (7). The variance on day  $t$ ,  $h_{it}$ , is conditional on the variance of the previous day,  $h_{i,t-1}$ , the size,  $|\epsilon_{it-1}|$  and the sign,  $\epsilon_{it-1}$ , of the most recent Abnormal Spread,  $AS_{it} = \epsilon_{it}$ . In a steady state, assuming the  $\epsilon_{it}$  is set equal to its expected value,  $E(\epsilon_{it}) = 0$ , and the variance constant over time:  $h_{i,t-1} = h_{it} = h_i$ , the unconditional variance for each company,  $i$ , subject to disclosure is:

$$h_i = e^{\left(\frac{\alpha_i}{1-\eta_i}\right)}. \quad (9)$$

According to the E-GARCH model, a large change in the abnormal spread,  $\epsilon_{it}$ , causes an increase of volatility of CDS quotes which is measured by the GARCH coefficient  $\beta_1$  and by the asymmetry coefficient,  $\beta_2$ . Any big change in the abnormal spread will have a persistent effect on the CDS dynamics, raising abnormal spread changes for a number of days afterwards. The degree of persistence depends on the size of the coefficient  $\eta$ . When  $\eta$  is relatively large, volatility takes a long time to fade away following an announcement in the market.

The estimated time dependent variance differs across companies and events. The values of  $\theta$  estimated for each company and each event are reported in Tables 4 and 5. Specifically, in Table 4, are reported the average values of

1  
2  
3  
4  
5  
6  
7  
8  
9 each parameter computed for companies of different rating class in the case of  
10 downgradings for the entire sample, which is divided into two subperiods: pre-  
11 crisis and post-crisis. In Table 5, corresponding statistics refer to the reviews.  
12

13  
14 The various E- GARCH parameters across the various companies show the  
15 dominant impact of the occurrence of shocks, or large changes in Abnormal  
16 Spreads. The estimates of the GARCH coefficient,  $\beta_1$ , and the asymmetry  
17 component,  $\beta_2$ , show the largest average values showing that Abnormal Spread's  
18 volatility is driven by the occurrence of a change in the  $AS_{t-1}$ . For instance, in  
19 the case of *A rated* companies the mean value of the  $\beta_1$  coefficients across com-  
20 panies is 0.906, and the mean value for  $\beta_2$  is 0.532. The degree of persistence,  
21 measured by the coefficient  $\eta$  is on average much lower. In the case of announce-  
22 ments regarding the downgrading  $\eta = 0.266$ , while for reviews the average  $\eta$  is  
23 equal to 0.092.  
24  
25

26  
27 The class of rating was not found to influence changes in volatility, the main  
28 driver is the occurrence of shocks at time  $t - 1$ , which affects the variance for a  
29 number of days afterwards.  
30  
31

## 38 5 Some results

39  
40 We carried out the *J-test* on the events in the sample. Tests for subgroups of  
41 events were also performed by rating class and geographical area. It is clear  
42 that European and US markets have different features in terms of liquidity and  
43 investors reaction may depend on the credit grade of the company.  
44  
45

46  
47 The analysis aims to verify the assumption that market participants some-  
48 how anticipate rating announcements. Table 6 gives the results of the *J-test* for  
49 the entire sample.  
50  
51

52  
53 INSERT TABLE 6 ABOUT HERE  
54  
55

56 For all the companies (*A+B rated*), the *J-test* was statistically significant  
57 for both reviews for downgrading and effective downgradings in intervals  $I_5$   
58 and  $I_6$ . This clearly demonstrates that CDS quotes show Abnormal changes  
59 right around the event date and in the days following. However, some evidence  
60  
61

1  
2  
3  
4  
5  
6  
7  
8  
9 suggests a different reaction by the market to reviews compared to downgrades.  
10 In the case of reviews significant changes were found in the intervals  $I_1$  and  $I_2$ ,  
11 but no effects were detected in the intervals  $I_3$  and  $I_4$ . The opposite results  
12 were found for downgradings. We conclude that market participants anticipate  
13 the occurrence of reviews for downgrading sixty to ninety business days before  
14 the event and then react heavily, as shown by the size of the average Abnormal  
15 Spread changes, around and after the event date. We further conclude that  
16 the effective downgrading is reflected in the change of CDS quotes up to forty  
17 business days before the event and some effects take place also after that.  
18  
19

20  
21  
22  
23 For companies belonging to different classes of rating (Panels A and B in Ta-  
24 ble 6), it is interesting to note different results for reviews for downgrading and  
25 downgradings. For *A rated* companies which were downgraded the CDS mar-  
26 kets seem to anticipate the occurrence of the event three months in advance,  
27 the only significant statistics refer to  $I_2$ . In the case of *B rated* companies the  
28 CDS markets seem to anticipate the downgrading over a shorter time interval  
29 ( $I_3 =$  two months), but the effects continue to be relevant given the significant  
30 statistics reported also in the intervals  $I_4, I_5$  and  $I_6$ . This shows that downgrad-  
31 ing of *Brated* companies strongly affects investor reactions, who perceive the  
32 downgrading as the beginning of serious risk and therefore keep requiring an  
33 additional spread. This may also be due to the special period considered in the  
34 analysis given the gravity of the current financial crisis making investors more  
35 sensitive to poor company performances. This was not found to occur with *A*  
36 *rated* companies which may be perceived as safe havens at this time.  
37  
38  
39  
40  
41  
42  
43  
44

45 Tables 7 and 8 report the results of the *J*-test by geographical area. Different  
46 results are found for the US market where CDS quotes seem to react promptly  
47 to rating announcements. In the case of *A rated* companies (Panel A table 7) it  
48 is interesting to note that reviews for downgrading are reflected in market quotes  
49 some one to three months ahead of the event, while no post-announcement effect  
50 was found. For *B rated* companies (Panel B, Table 7) effective downgradings  
51 seem to affect the market's behavior only in the intervals around the event and  
52 no great anticipation occurs.  
53  
54  
55  
56  
57

58 Results for the European markets (Table 8) show that participants anticipate  
59 reviews in the intervals  $I_1, I_2, I_3$  and  $I_5$ , showing significant abnormal spread  
60

### 17 **5.0.1 Conditional Variance**

18  
19 The results of the  $J$ -test should be analyzed in conjunction with the behavior of  
20 the conditional volatility, which can provide very useful information. The condi-  
21 tional variance estimated for each Abnormal Spread series accurately describes  
22 the volatility dynamics over the entire period (EP+TP) for each company, suc-  
23 cessfully capturing the change in volatility occurring around the event date.  
24 In Figures 9–12 examples of how the conditional volatility behaves around the  
25 event date for three *B rated* companies is shown.  
26  
27

29  
30  
31

32  
33 INSERT FIGURE 9 ABOUT HERE

34  
35 INSERT FIGURE 10 ABOUT HERE  
36

37  
38 Using the E-GARCH parameters, we calculated the long run unconditional  
39 variance,  $h_i = e^{\left(\frac{\alpha_i}{1-\eta_i}\right)}$ , and made a useful comparison with the conditional  
40 variance. In Figure 9 and 10 we report the conditional and the unconditional  
41 variance around a specific downgrading event for two *A rated* companies. For  
42 these two companies the conditional volatility results are always larger than the  
43 unconditional volatility and different patterns occur some three months before  
44 the events. In the case of EON (see Figure 9) the conditional volatility starts  
45 to show completely different dynamics some sixty days before the event, with a  
46 large spike occurring twenty days before the event. In the case of AMEX (Figure  
47 10) the change in volatility dynamics also occurs three months before the event,  
48 in this case the largest increase occurred sixty days before the event. In both  
49 examples no changes in volatility behavior is observed in the days following the  
50 event. This is found for all of the *A rated* companies. The E-GARCH model  
51 provides the most accurate measure of the Abnormal Spread volatility and this  
52 was also confirmed by the  $J$  test for *A rated companies*, results being statistically  
53  
54

11

12  
13  
14 INSERT FIGURE 11 ABOUT HERE

15  
16  
17 INSERT FIGURE 12 ABOUT HERE

18  
19 In Figures 11 and 12 the conditional and unconditional variance for two  $B$   
20 *rated* companies are reported. It is interesting to note that for  $B$  *rated* companies  
21 the variance dynamics changes forty days before the event and in some cases,  
22 as with MGM for example, the entire dynamics are subsequently altered. In  
23 this case a different approach to study the CDS volatility dynamics should be  
24 used, for instance a study of structural breaks in the volatility should provide  
25 more accurate results. This is beyond the scope of this study, but the authors  
26 are analyzing it for a subsequent paper. Similar results were found for other  
27 companies, confirming the results reported in Table 6 (Panel B), where the  
28  $J$ -test for  $B$  *rated* companies was statistically significant for intervals  $I_3$ ,  $I_4$   
29 and  $I_5$ . The results obtained support our assumption that CDS quotes are  
30 exceptionally volatile once a rating agency's eye is put on a specific company.  
31 When this occurs, Abnormal Spread volatility changes should be monitored  
32 more than the Abnormal Spread changes, in and of itself.  
33

42

## 43 **6 Conclusions**

44  
45  
46 We demonstrate how using conditional variance modeling in the Event Study  
47 methodology yields more accurate results. The volatility represents a key ele-  
48 ment in the assessment of Abnormal Spread changes.  
49

50  
51 Overall, rating announcements have an effect on CDS quotes mainly around  
52 the event date. In the case of reviews, some anticipatory effects, up to five  
53 months ahead, were found.  
54

55  
56 In general, European companies appear to be less sensitive to rating agency  
57 news when compared to US companies.

58  
59 The critical factor is the conditional variance and the E-GARCH model  
60 which succeeds best in tracking the changes in variances around event dates.  
61  
62

1  
2  
3  
4  
5  
6  
7  
8  
9 Additionally, the conditional variance of each company provided more effective  
10 signals of the feelings portrayed in the market place than the unconditional long  
11 run variance level.  
12

13  
14 Our results encourage us to further investigate the role of volatility in provid-  
15 ing information about market behavior. Additional analysis will be conducted  
16 to investigate the existence of structural breaks in the conditional Abnormal  
17 Spread variance.  
18  
19

Table 4. E-GARCH parameters around downgradings by rating class

Panel A: 2004-2009 - Downgrades	Mean Value A-rated	Mean Value B-rated
Garch Parameter $\beta_1$	0.906	0.831
Asimmetry Parameter $\beta_2$	0.532	0.581
Constant $\alpha$	0.265	0.508
Persistence Parameter $\eta$	0.266	0.273
Panel B: 2004-2006 - Downgrades	Mean Value A-rated	Mean Value B-rated
Garch Parameter $\beta_1$	0.972	0.839
Asimmetry Parameter $\beta_2$	0.225	0.746
Constant $\alpha$	0.088	0.866
Persistence Parameter $\eta$	0.210	-0.035
Panel C: 2007-2009 - Downgrades	Mean Value A-rated	Mean Value B-rated
Garch Parameter $\beta_1$	0.912	0.836
Asimmetry Parameter $\beta_2$	0.563	0.563
Constant $\alpha$	0.359	0.511
Persistence Parameter $\eta$	0.284	0.138

Table 5

[Click here to download high resolution image](#)

Table 5. E-GARCH parameters around reviews for downgrading by rating class

Panel A: 2004-2009 - Reviews	Mean Value A-rated	Mean Value B-rated
Garch Parameter $\beta_1$	0.882	0.752
Asimmetry Parameter $\beta_2$	0.602	0.598
Constant $\alpha$	0.204	0.381
Persistence Parameter $\eta$	0.092	0.056
Panel B: 2004-2006- Reviews	Mean Value A-rated	Mean Value B-rated
Garch Parameter $\beta_1$	0.867	0.802
Asimmetry Parameter $\beta_2$	0.377	0.408
Constant $\alpha$	0.031	0.728
Persistence Parameter $\eta$	0.110	0.103
Panel C: 2007-2009- Reviews	Mean Value A-rated	Mean Value B-rated
Garch Parameter $\beta_1$	0.890	0.726
Asimmetry Parameter $\beta_2$	0.699	0.721
Constant $\alpha$	0.295	0.197
Persistence Parameter $\eta$	0.082	0.031

Table 6. CDS market reaction around rating events (2004-2009)

Sub-intervals		I <sub>1</sub>	I <sub>2</sub>	I <sub>3</sub>	I <sub>4</sub>	I <sub>5</sub>	I <sub>6</sub>
Classes of rating		[-90, -61]	[-60, -41]	[-40, -21]	[-20, -2]	[-1, 1]	[2, 20]
